ABSTRACT

Global warming is primarily caused by greenhouse gases such as CO₂. One smart solution to mitigate its impact is to convert CO₂ into hydrocarbons through photoreduction processes. In this work, CO₂ was photo-catalytically reduced over new aerogel-based materials to produce methanol, using a solar simulator and a specifically designed photoreactor.

Cu-loaded Nb and N co-doped TiO₂ aerogels (Cu/ATiO₂: Nb, N) were synthesized by the sol-gel method followed by supercritical CO₂ drying and annealing in a controlled atmosphere. The obtained photocatalysts benefit from the peculiar properties of aerogels with high specific surface area (88 m²/g) and porosity. N and Nb doping improved the electronic and optical properties, resulting in a significantly improved visible light absorption compared to pure TiO₂ aerogel (ATiO₂) or commercial catalyst P25. Cu_xO nanoparticles, smaller than 5 nm and uniformly distributed on the surface of aerogels, contribute to the improvement of the conversion efficiency. Used for CO₂ photoreduction, one of the best-reported methanol yields (1.69 ± 0.05 mmol/g_{cat}/h) was obtained, and the impact of Cu, Nb, and N on methanol production was studied.

1. Introduction

Carbon dioxide (CO₂) is a major greenhouse gas that contributes to global warming and climate change [1]. Therefore, it is imperative to find a green, economical, and efficient solution for its conversion and utilization. However, CO₂ is the most thermodynamically stable compound of carbon with a standard enthalpy of formation of −393.5 kJ/mol and a C=O Bond energy E = 803 kJ/mol (298.15 K). Hence, the activation of CO₂ requires a lot of energy [2,3]. Traditional methods (e.g., thermal catalysis) are not efficient. On the contrary, artificial photosynthesis enables CO₂ reduction under mild conditions [4,5]. Therefore, developing efficient and stable photocatalysts that convert CO₂ into useful fuels such as formic acid, methane, formaldehyde, methanol, ethanol, etc. is crucial for the development of CO₂ photoreduction processes.

Among different semiconductors, titanium dioxide (TiO₂), with a band gap of 3.2 eV in its anatase form, has attracted considerable attention due to its abundance, low cost, high stability, and wide applicability [6]. Inoue et al. observed in 1979 that CO₂ can be catalytically converted to methanol and formic acid using TiO₂ as a photocatalyst [7], paving the way to its utilization in this area. However, raw

TiO₂ has low visible light absorption, due to its wide bandgap, which leads to fast recombination of photogenerated charge carriers and shows low CO₂ adsorption capacity [8,9]. To overcome these drawbacks, many strategies have been proposed to modify TiO₂, such as doping [10], heterojunction formation [11], surface modification [12], and hybridization with other materials [13].

The doping of TiO₂ with various elements can increase its photocatalytic activity from the creation of new energy levels in the bandgap. Such energy levels can be located either near the conduction or the valence band [14] depending on the type of dopant, like metal [15,16] and non-metal [17,18]. For example, doping TiO₂ with silver (Ag) can enlarge its visible light absorption range, lowering the bandgap to 2.5 eV [19]. Moreover, the creation of Ti–Ag–O also promotes more efficient charge transfer and separation after irradiation [19]. Similarly, Lanthanum (La) doping was reported to impact the structural, optical, and photoluminescence properties of TiO₂ nanocrystals [20]. Lattice-doped TiO₂ nanofibers with enhanced photocatalytic properties effectively convert N₂ to NH₃ (14783 μmol/L/g_{cat}) under visible light [21].

Niobium (Nb⁵⁺) (0.64 Å) has a similar ionic radius to Ti⁴⁺ (0.605 Å), allowing doping by substitution [22,23]. Such doping will generate Nb_{Ti}

defects compensated with additional free electrons in TiO₂. These free electrons can be trapped by Ti⁴⁺ or oxygen vacancies (V_O^{••}) to generate respectively Ti³⁺ or V_O[•]. Because Nb⁵⁺ is an electron donor, the introduction of Nb can increase the electrical conductivity of the samples [24, 25] Nb⁵⁺ doping might also introduce interstitial O defects, [26] with energy states lying upon the VB of TiO₂, giving rise to yellow samples [27]. With increasing Nb concentration, the optical band gap becomes increasingly narrow (2.93 eV → 2.75 eV for 10 mol% Nb) [28]. Nb-doped TiO₂ microspheres have been reported to exhibit higher photocatalytic rates than undoped TiO₂ for the degradation of gaseous acetaldehyde [28].

However, the concentration of the dopant in the host matrix has to be precisely controlled. Indeed, too high a concentration can result in a quenching of the expected property and introduce excessive structural defects which can affect the stability of the crystal.

For non-metal doping, C-doping can introduce oxygen vacancies and defects in TiO₂, which can also increase visible light absorption and surface reactivity [29]. N-doping can create new energy levels or modify the band structure of TiO₂, which can facilitate the transfer and separation of charge carriers and reduce their recombination rate [30–33]. Co-doping with metal and non-metal elements is also an option for modifying TiO₂. N, Eu co-doped TiO₂ enhanced photocatalytic reduction of CO₂ into CH₄ (13.48 μmol·g⁻¹·h⁻¹), which was reported to be about 12 times higher than that of pure TiO₂, thanks to the synergistic effect of Eu and N. The modification did not only effectively increase the surface area of N-Eu/TiO₂ and inhibit crystallization of TiO₂, but also reduced the band gap of TiO₂ [34].

As another example, Ce/N co-doping highly affects the structure and activity of TiO₂. As the Ce concentration in the catalyst was increased the crystallinity and crystal size of the co-doped samples decreased with an increase in BET specific surface area [35]. Depositing metal (e.g. Fe, [36] Cu, [37] Ag, [38] Au, [39] and Pt [40]) on the surface of TiO₂ is also an appropriate method for improving the separation of electron-hole pairs through the established metal-semiconductor Schottky junction. This not only helps extract the photogenerated electrons but also dramatically reduces the energy barrier for proton reduction.

In the realm of photocatalytic materials, the surface area plays a pivotal role, with a higher surface area correlating to increased catalytic activity [41–44]. In photocatalytic CO₂ reduction, TiO₂ aerogels are distinguished by their high specific surface areas (S_{BET}), which markedly enhance their photocatalytic performance [45]. 3D structured TiO₂-based aerogel photocatalyst showed a high efficiency for the degradation of toluene gas. The toluene-removal rate of Pt-TiO₂/RGO aerogel was 60% higher than that of the pure RGO aerogel, and 56% higher than that of the bare TiO₂ nanofibers [46]. Pd-TiO₂ aerogels are approximately 3.5-fold more active for H₂ evolution than Pd-TiO₂ powders, giving evidence that the porous structure favors light-harvesting and reagent transport, making them superior photocatalysts [47].

Aerogels are known to exhibit large specific surface area and pore volume, which can be highly beneficial for CO₂ adsorption and activation, enlarging the contact surface between the reactants and the catalyst. [48,49] In this paper, we report the synthesis and characterization of a new photocatalyst, developed based on the previous work of our group [50].

Nb, N-codoped TiO₂ aerogels were prepared to support Cu oxides (Cu_xO) nanoparticles deposited through an in-situ synthesis route. TiO₂ aerogels are recognized as highly porous materials, which can enhance light absorption and charge separation [45].

Here, we have studied the combined role of doping TiO₂ aerogels with niobium and nitrogen with that of Cu_xO nanoparticles deposited on their surface. The photocatalytic activity of as-prepared photocatalysts was investigated for photocatalytic reduction of CO₂. Notably, this methodology resulted in one of the best-reported methanol yields, achieving an impressive rate of 1.69 ± 0.05 mmol/g_{cat}/h. The relation between the structure, morphology, optical properties, and

photocatalytic activity was discussed in detail.

2. Experimental section

2.1. Chemicals

All chemicals were of analytical grade and used without further purification. Copper nitrate (Cu(NO₃)₂•3 H₂O, Alfa Aesar), Nitric acid (HNO₃, 2 M, Alfa Aesar), Tetrabutyl titanate (Ti(OBu)₄, C₁₆H₃₆O₄Ti, Alfa Aesar), Niobium isopropoxide (Nb(OiPr)₅, C₁₅H₃₅NbO₅, 10% w/v in isopropanol/hexane (50:50) (10 at%), Alfa Aesar), Absolute ethanol (CH₃CH₂OH, Alfa Aesar), Isopropanol (iPrOH, C₃H₈O, Alfa Aesar), Deionized water (D.I., Homemade), Argon (Ar, 99.9999%), Ammonia (NH₃, 10 w.t. % in N₂).

2.2. Preparation of catalysts

Aerogels were synthesized starting from a classical sol-gel route based on alkoxides, [51] and already experienced in a previous study [52]. The following parameters have been selected for the whole study: R = H₂O/Ti(OBu)₄ = 3.4 (mol/mol), C = HNO₃/Ti(OBu)₄ = 0.07 (mol/mol), and S = iPrOH/Ti(OBu)₄ = 15 (mol/mol).

Briefly, 10.96 ml of Ti(OBu)₄, 10.01 ml of Nb(OiPr)₅, and 0.382 g Cu (NO₃)₂•3 H₂O (5 wt%) in 15 ml iPrOH were mixed with thorough stirring and noted as solution A. Similarly, 0.84 ml D.I. water, 1.12 ml HNO₃, and 16 ml iPrOH were mixed with thorough stirring to obtain a solution marked as B.

Solution B was added dropwise into solution A within 30 s, with vigorous stirring for 1 min, then left to stand for gelation. The resulting gel was aged at room temperature for 72 hours, and then washed with isopropanol 3 times a day for 3 days to remove H₂O and unreacted chemicals. Finally, supercritical CO₂ drying (SC CO₂) was carried out to obtain Nb-doped TiO₂ aerogel. Cu-contained aerogel samples were prepared with the addition of Cu(NO₃)₂ in solution A.

For N-doping, aerogels were calcined under NH₃ atmosphere for 45 mins at 550 °C (ramp-up and cool-down under N₂ at 5 °C/min). The obtained powder was labeled Cu/ATiO₂: Nb, N (A standing for aerogel). This post-treatment was named as NH₃ treatment. Cu/ATiO₂: N and ATiO₂: Nb, N were also obtained by applying this NH₃ treatment to corresponding aerogels. Other samples were calcined in Air (550 °C, 2 h) and labeled ATiO₂, ATiO₂: Nb, Cu/ATiO₂, and Cu/ATiO₂: Nb.

The list of samples is presented in Table 1.

2.3. Characterization

X-ray diffraction (XRD) patterns were collected using a powder diffractometer (MPD PANalytical X'Pert Pro) operated at 45 kV, with CuKα radiation (λ = 0.154 nm). Data were collected in steps of 0.05° from 10 ° to 90 ° in 2θ mode with Pixcel counter.

The X-ray photoelectron spectroscopy (XPS) analyses were carried out using a Thermo Scientific K-Alpha system. XPS analysis was repeated 5 times on the same sample. The positions of all binding energies were calibrated using the C1s line at 284.8 eV.

Scanning electron microscopy (SEM) observations were recorded

Scheme 1. Sketch schematic of test bench.

with a MAIA3 with a 3 kV electron beam. The composition has been analyzed by energy dispersive X-ray spectroscopy (EDX) at 15 kV, performed with a Philips XL30.

Transmission electron microscopy (TEM, Thermo Fisher Spectra 200, operated at 200 kV and equipped with a cold filed emission gun and a Cs aberration probe corrector) analyses in high resolution TEM (HRTEM) mode and in scanning TEM (STEM) mode.

Solid-state UV–visible diffuse reflectance spectra (UV-Vis DRS) were recorded at room temperature using the Cary 500 UV–VIS–NIR spectrophotometer. Polytetrafluoroethylene standard was used as the reference. The bandgap was determined according to Kubelka-Munk treatment. Two values for each sample were averaged. They were obtained by intersecting extreme tangents to the curve in the most vertical area with the horizontal coordinate.

Isothermal N₂ sorption experiments were performed with BELSORP MINI X. The BET model was applied to calculate the specific surface area of samples (S_{BET}). Each sample was tested twice to obtain an average value of S_{BET} .

2.4. Evaluation of catalytic performance

The catalytic reaction was carried out in a specifically designed

micro-autoclave equipped with sapphire windows and placed in a black box. Sketch schematic of test bench was present in Scheme 1. A 100 W Xe-light source (Oriell[®] LCS-100[™] Small Area Sol1A, Newport) was used as a solar simulator, the photocatalytic experiments were conducted under a broad range of wavelengths, encompassing the entire spectrum of light that the Xe lamp emits, thereby utilizing the complete range of photon energies available from UV to visible light. The photocatalyst (200 mg), and Na₂CO₃ (400 mg) were added in H₂O (100 ml) and sonicated for 30 min. The suspension was transferred into the reactor and purged with CO₂ (1 L/h) gas for 30 min in the dark. The lamp was then switched on to illuminate the sample and the temperature and the pressure were recorded during the experiment. Liquid aliquots were sampled at regular intervals using a sampling port at the bottom of the reactor and analyzed with high-performance liquid chromatography (HPLC, Shimadzu LC 20). The HPLC is equipped with a typical sugar column (HPLC Column SUGAR SH1821, 6 μm, 8 × 300 mm, Shodex) using 5 mM H₂SO₄ as mobile phase, a UV detector, and a refractive indexing detector (RID). The gas was analyzed using an Agilent 3000 A MICRO GC, which is equipped with a Thermal Conductivity Detector (TCD). The analysis revealed that methanol was the sole product identified in the reaction liquid, with no detectable products in the gas phase.

3. Results and discussion

Before evaluating their photocatalytic ability for CO₂ reduction, aerogel samples were deeply characterized.

3.1. Physicochemical characterization

All samples have been characterized with XRD, XPS, N₂ sorption, SEM, and TEM to analyze their morphology, composition, and structure which are important features considering the foreseen application.

Fig. 1 shows the X-ray diffraction spectra (XRD) of the different samples and P25 (Figure S3), TiO₂ aerogels doped with Nb and N (ATiO₂: Nb, N), and their counterparts loaded with Cu (Cu/ATiO₂: Nb, N). All patterns show the crystalline phase of Anatase TiO₂ (JCPDS 71–1168). No other oxide phase could be detected showing that Nb is most probably included in the crystalline structure of TiO₂. This is confirmed by the slight blue shift of the (101) peak at 25.2° (Fig. 1B), a shift only observed for the Nb-doped samples, as in our previous work

[50]. This can be ascribed to a cell distortion resulting from doping because the ionic radius of Nb⁵⁺ (0.64 Å) is slightly larger than that of Ti⁴⁺ (0.605 Å).

The (110) peak of Rutile was clearly observed for the samples doped only with N, ATiO₂: N, and Cu/ATiO₂: N. It appears much weaker on other samples. The NH₃ treatment may lower the TiO₂ phase transfer temperature which should rise above 600 °C. We have already experienced such an effect of a reducing calcination atmosphere in our previous work [50]. This peak appears with a much lower intensity on XRD patterns of other samples, even those co-doped with N, ATiO₂: Nb, N and Cu/ATiO₂: Nb, N. For the latter, this may result from the presence of Nb, which in turn is increasing the TiO₂ phase transfer temperature as also reported in our previous study, thus probably here counterbalancing the effect of NH₃ treatment [50].

In all Cu-loaded samples, the peaks of Cu_xO were not observed, maybe due to the small size of the Cu_xO particles, uniformly distributed in the sample.

As shown in Table S1, the crystallite size calculated from the (101)

Fig. 3. Cu 2p XPS spectra of Cu loaded ATiO₂, ATiO₂: N, ATiO₂: Nb and ATiO₂: Nb, N.

peak is very similar for all samples, close to 12 nm. There is no significant effect either of the doping or the metal loading.

The Ti 2p X-ray photoelectron spectra (XPS) of all samples show peaks at ~464.3 eV and ~458.5 eV attributed to Ti⁴⁺ Ti 2p_{1/2} and Ti 2p_{3/2} respectively (Fig. 2A) [53]. As presented in Table 2, their positions are very similar whatever the samples. The doping or the presence of Cu seems to not affect the binding energy of Ti in the analyzed samples.

The XPS O 1s peak can be separated into two peaks at ~529.8 eV and ~530.8 eV corresponding to lattice oxygen (O_L) and oxygen vacancies (O_V) respectively (Fig. 2B) [54]. The latter (O_V) appears only for doped samples, as a result of charge balancing, thus evidencing the successful doping of the samples. As for Ti 2p, no significant shift in the position of the O species peaks was observed for the different samples, (Table 2), except for samples doped only with N, ATiO₂: N, and Cu/ATiO₂: N.

Nb could be detected in our samples (Fig. 2C). The peaks at ~209.9 eV and ~207.2 eV are attributed to Nb⁵⁺ Nb 3d_{5/2} and Nb 3d_{3/2} respectively [55]. Here also, still no significant shift in the peak positions as presented in Table 2.

After N-doping, a peak corresponding to N 1s was expected at ~400 eV [56]. If this peak can clearly be observed in Fig. 2D for ATiO₂: N, it can hardly be detected for other N-doped samples, maybe due to only a very small amount of N introduced in the TiO₂ lattice.

The XPS spectra of Ti 2p, O 1s, and Nb 3d are not different between ATiO₂, ATiO₂: Nb, ATiO₂: Nb, N, Cu/ATiO₂, Cu/ATiO₂: N, Cu/ATiO₂: Nb, and Cu/ATiO₂: Nb, N, indicating that the surface electronic

structure of as-prepared catalysts before and after doping and loading remain stable, which is an important property of photocatalysts.

Fig. 3 shows the Cu 2p XPS spectra obtained for the samples loaded with Cu: Cu/ATiO₂, Cu/ATiO₂: N, Cu/ATiO₂: Nb, and Cu/ATiO₂: Nb, N. The peaks for Cu 2p_{1/2} and Cu 2p_{3/2} were separated to bring out peaks corresponding to Cu²⁺ and Cu⁺. Detailed information on the peak position is presented in Table 3 and Table S2.

Taking Cu 2p_{3/2} as an example, the peak at ~934.10 eV is attributed to Cu²⁺ and the peak at ~932.20 eV is attributed to Cu⁺ [57]. The peak position of Cu²⁺ and Cu⁺ both shifted to a lower binding energy (redshift) after N doping: see the comparison between Cu/ATiO₂: N and Cu/ATiO₂ (-0.99/-0.85 eV for Cu²⁺ 2p_{1/2}/2p_{3/2}, -1.12/-0.57 eV for Cu⁺ 2p_{1/2}/2p_{3/2}) and between Cu/ATiO₂: Nb, N and Cu/ATiO₂: Nb (-0.37/-0.59 eV for Cu²⁺ 2p_{1/2}/2p_{3/2}, -0.33/-0.50 eV for Cu⁺ 2p_{1/2}/2p_{3/2}). This red shift represents an increase of the electron density around Cu, resulting from a modification of their local chemical environment after NH₃ treatment [58]. Considering the difference in electronegativity between N (3.04) and O (3.44) it is supposed to replace in TiO₂ structure, [59] we may see here another evidence of N-doping. Moreover, this would indicate a close connection of Cu with N or O in the structure.

It is also clear from Fig. 3 that an inversion of the Cu²⁺ and Cu⁺ peak relative intensity arose after NH₃ treatment compared to samples calcined under air. Note that an intermediate value was obtained after calcination under N₂ (0.97), see Table 3 and Figure S1. The comparison revealed a higher Cu⁺ content for the samples calcined under NH₃, showing a reduction of Cu²⁺ during the treatment, in agreement with the modification of the electron density around Cu described before.

The specific surface area (S_{BET}) of our samples was analyzed concerning their composition and compared to that of P25 (Fig. 4). The N₂ sorption isotherms of Cu/ATiO₂: Nb, N curve was shown in Figure S4. The higher the S_{BET} the better for photocatalytic performance.

Confirming the expected properties of aerogels, [45] our obtained TiO₂ aerogel (ATiO₂) showed a higher S_{BET} (92 m²/g) than the

Fig. 5. SEM images and Particle size distribution of synthesized samples (A₁) ATiO₂, ATiO₂: N, ATiO₂: Nb, and ATiO₂: Nb, N, (B₁) Cu loaded counterparts. *Particle size distribution was statistics based on counting 200 particles.

Fig. 6. (A) HAADF-STEM image of Cu/ATiO₂: Nb, N, (B) Measured Cu_xO particle size and (C) EDS elemental mapping of Ti (D), Cu (E), and Nb (F).

commercial catalyst P25 (51 m²/g). The S_{BET} was significantly increased after doping with Nb (1.23 m²/g for ATiO₂:Nb), in agreement with our previous study [50]. Present in Table 4, is the S_{BET} value in the literature, TiO₂ aerogels have an obviously high surface specific area.

The Cu-loaded samples maintained a high specific surface area, 74 and 96 m²/g respectively for Cu/ATiO₂ and Cu/ATiO₂: Nb, despite a notable decrease of about 20%.

The NH₃ post-treatment, applied to dope samples with N resulted in a slight decrease of the specific surface area, -5 m²/g for Cu/ATiO₂: N (69 m²/g), -16 m²/g for ATiO₂: Nb, N (107 m²/g) and -8 m²/g for Cu/ATiO₂: Nb, N (88 m²/g), which is quite reasonable.

Such a systematic decrease can be accounted for the temperature of the NH₃ treatment which is responsible for a slight particle size increase as evidenced by the SEM pictures (Fig. 5).

Fig. 5 presents the SEM images for ATiO₂ and its various doped forms, including ATiO₂: N, ATiO₂: Nb, and ATiO₂: Nb, N, as well as their Cu-loaded variations. Consistent with our previous studies [50], the TiO₂ aerogels display a texture that appears relatively dense due to the agglomeration of roughly spherical particles and looks slightly dense. The apparent density is however difficult to measure since the monolithic nature was lost during supercritical drying and calcination.

The particle size of our aerogels stands between 22 nm and 30 nm with quite uniform distribution. The doping with Nb leads to a decrease in the particle size of TiO₂ aerogels from 25 to 22 nm in diameter (modulo the accuracy of the method), which is consistent with the conclusion of N₂ sorption analysis (Fig. 4). Except for Cu/ATiO₂: Nb, N, the presence of Cu did not impact the mean particle size of the samples. The small size of the particles, on top of resulting in a large specific surface area, is beneficial to the refraction of the incident light on the catalyst surface, thus improving the photocatalytic efficiency [63].

The presence of Cu in the samples was confirmed by TEM observations which also gave some information on the size of the Cu_xO particles (Fig. 6).

Fig. 6A shows the HAADF-STEM image of Cu/ATiO₂: Nb, N. Two families of lattice spaces could be analyzed. The lattice space of 0.354 nm corresponds to Anatase TiO₂ (101) [64]. The lattice spaces of 0.246 nm and 0.232 nm can be attributed to CuO (111) and Cu₂O (111), respectively [65], in agreement with the results obtained by XPS (Cu 2p, Fig. 3). Comparison between Fig. 6B, C, and E, led to the conclusion that the small particles observed in Fig. 6B most probably correspond to Cu_xO. Their diameter roughly stands between 1.5 and 3 nm, which confirms the difficulty of detecting any Cu_xO species with XRD (Fig. 1).

Nb could be detected (Fig. 6F), apparently uniformly distributed over

the image. The amount is however too small to discuss further.

The presence of Cu_xO species as homogeneously dispersed nanoparticles may facilitate the CO₂ reduction reaction and contribute to the fast migration of intermediate species for better efficiency.

3.2. Optical characterization

UV-vis diffuse reflectance spectroscopy (UV-Vis DRS) was used to characterize the domain of light absorption of our materials and to determine their bandgap (Fig. 7).

A strong adsorption band (< 400 nm) is found for all samples (Fig. 7 A), which is caused by the intrinsic interband absorption of TiO₂ [66].

Our TiO₂ aerogel absorbs a little bit more light than P25 and even a little bit more after Nb doping. The difference in absorption between ATiO₂ and its doped/loaded counterparts is represented in Fig. 7B. The data processing applied (subtraction of the ATiO₂ absorption data) revealed an absorption band at around 380 nm for ATiO₂: Nb. This effect is probably due to the slight shift of the absorption edge which should result in a change in bandgap (Table 5).

After NH₃ treatment (ATiO₂: N), a new absorption band appeared clearly at around 440 nm (Fig. 7 A) which is amplified in Fig. 7B, as is the band at 380 nm due to a further shift of the absorption edge. This result can be considered as another evidence of N-doping even though N could hardly be detected by XPS.

Both phenomena are amplified for Nb, N-co-doped TiO₂ aerogel whose absorption is much stronger in the visible domain, as if a synergistic effect was at work.

The Cu-loaded samples (Cu/ATiO₂, Cu/ATiO₂:Nb, Cu/ATiO₂:N and Cu/ATiO₂: Nb, N) show some additional absorption in the range of 400 – 550 nm, which has already been observed by Li et al., [67] and attributed to the charge transfer from the valence band (VB) of TiO₂ to copper oxide nanoparticles. The absorption increased after Nb and N doping.

In the case of Cu/ATiO₂ and Cu/ATiO₂: Nb, which were not treated under NH₃, another absorption appeared in the range of 600 – 800 nm. This phenomenon can be associated with the intrinsic exciton band of CuO and the d-d transition of the Cu²⁺ species [68].

All these observations are consistent with the color of each sample (Fig. 7D). From ATiO₂ to ATiO₂: Nb, N, the samples' color shifts from white to beige due to a slight increase of absorption in the visible domain. The Cu-loaded samples absorb much more light. A minimum of absorption can be observed for Cu/ATiO₂ and Cu/ATiO₂: Nb in the green range of the visible spectrum (around 550 nm) which makes them

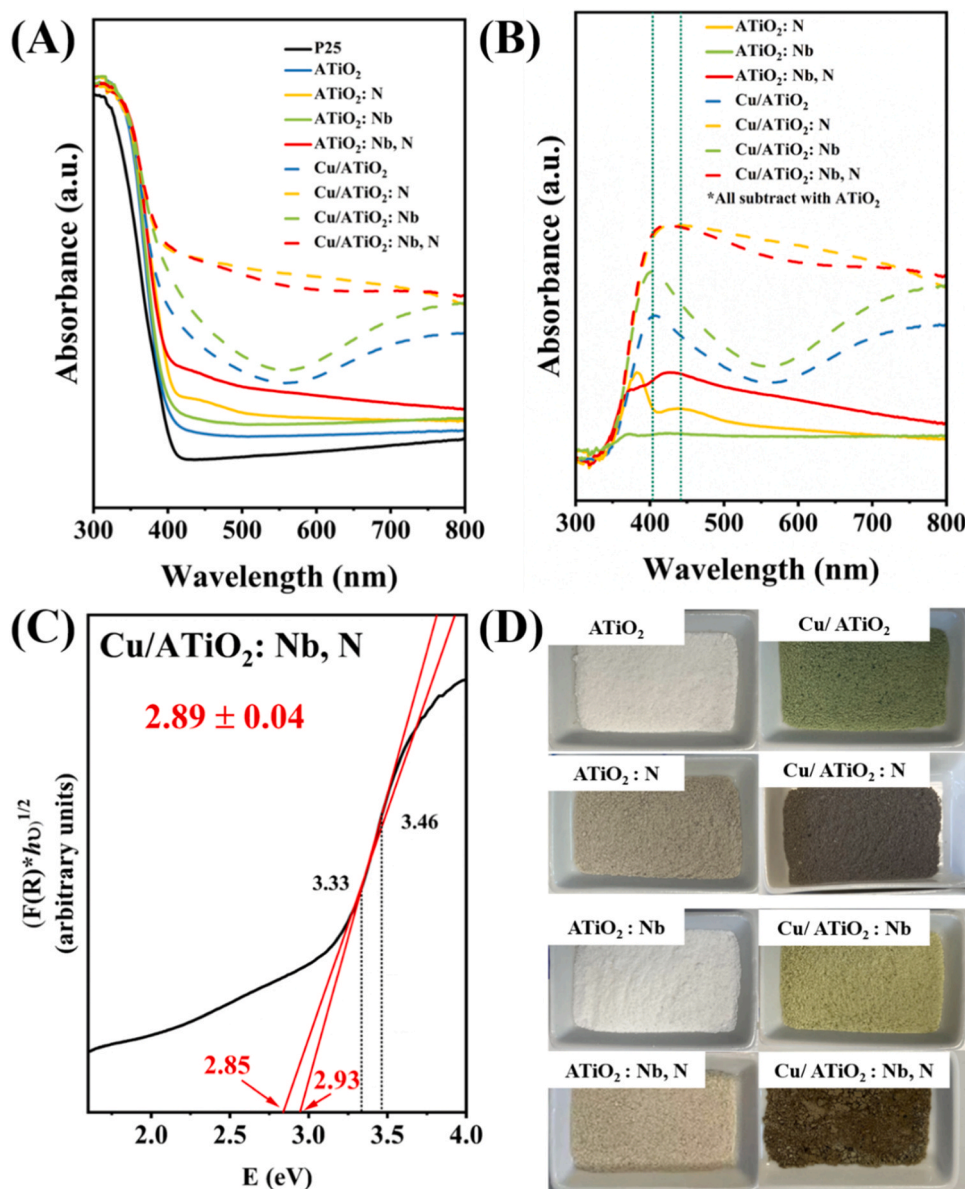

Fig. 7. (A) UV-vis diffuse reflectance spectra (UV-Vis DRS) of synthesized samples and P25, (B) spectra obtained after subtraction of that of ATiO₂, (C) Plot of the transformed Kubelka-Munk functions vs. the energy of light of Cu/ATiO₂: Nb, N and (D) samples images of ATiO₂, ATiO₂: N, ATiO₂: Nb, ATiO₂: Nb, N, Cu/ATiO₂, Cu/ATiO₂: N, Cu/ATiO₂: Nb and Cu/ATiO₂: Nb, N.

Table 5
Band gap of P25 and as prepared samples.

Samples	Band gap (eV)
P25	3.03 ± 0.02
ATiO ₂	3.04 ± 0.02
ATiO ₂ : N	3.00 ± 0.06
ATiO ₂ : Nb	3.00 ± 0.09
ATiO ₂ : Nb, N	2.97 ± 0.05
Cu/ATiO ₂	2.96 ± 0.04
Cu/ATiO ₂ : N	2.92 ± 0.08
Cu/ATiO ₂ : Nb	2.93 ± 0.08
Cu/ATiO ₂ : Nb, N	2.89 ± 0.04

appear green. The samples treated in a reducing atmosphere (NH₃ treatment, Cu/ATiO₂: N and Cu/ATiO₂: Nb, N) do not show such a minimum and appear brown to dark grey.

The difference in light absorption observed for these different materials has an impact on their bandgap. This can be evidenced after

Kubelka-Munk processing of the absorption data (Fig. 7 C and Table 5). Note that the bandgap values obtained for Cu-loaded samples have to be taken with caution since the presence of Cu oxides makes difficult the determination with Kubelka-Munk data treatment.

The absorbance spectrum of P25 shows a steep decrease between 350 and 400 nm, resulting in a bandgap of 3.03 eV in good agreement with previously reported data [69].

That of TiO₂ aerogel (ATiO₂) is very close (3.04 eV). It is clear from Fig. 7 A and 7D that the co-doping of ATiO₂, with Nb and N, enlarged the range of light absorption of TiO₂. As a consequence, its bandgap appeared to be slightly narrower than that of ATiO₂ and P25 with a value of 2.97 eV. Considering the accuracy of the calculation, it is difficult to sort these materials. However, with a value of 2.97 eV, the bandgap of ATiO₂: Nb, N is no doubt smaller than the expected one of 3.2 eV for classical anatase TiO₂. [70] The situation is even better after Cu deposition due to the charge transfer effect. The estimated bandgap of Cu/ATiO₂: Nb, N dropped to about 2.9 eV (provided that Cu oxides do not interfere with TiO₂), the smallest of all samples synthesized in this

Fig. 8. (A) Photocatalytic evaluation via reduction of CO₂ under simulated Solar Light on synthesized materials compared to P25, the embedded figure representing the relationship between Methanol (MeOH) yield and Cu⁺/Cu²⁺ ratio over Cu/ATiO₂: Nb, N, (B) MeOH yield per hour on Cu/ATiO₂: Nb, N.

study.

The bandgap of Cu/ATiO₂ doped with Nb or N, Cu/ATiO₂: Nb and Cu/ATiO₂: N, would stand in between that of Cu/ATiO₂ (2.96 eV) and that of Cu/ATiO₂: Nb, N (2.9 eV).

The doping with Nb is expected to decrease the bottom of the conduction band (CB) of TiO₂, while N doping should increase the top of the valence band (VB) of TiO₂ [17]. Thus, by doping with both Nb and N, the band gap of TiO₂ is expected to become narrower, improving the light absorption performance.

3.3. Performance evaluation of photocatalytic CO₂ reduction

Fig. 8A presents the performance of different photocatalysts to produce methanol (MeOH) through CO₂ photoreduction. Note that here we directly used a solution of Na₂CO₃ instead of directly bubbling CO₂ into H₂O as sometimes reported in the literature. The temperature does not exceed 35°C during the whole test (see Figure S2). In this work, the production rate was calculated throughout 6 h of illumination.

Undoped ATiO₂ showed a similar performance to the commercial catalyst P25 (0.03 ± 0.01 mmol_{MeOH}/g_{cat}/h vs 0.02 ± 0.01 mmol_{MeOH}/g_{cat}/h), indicating that TiO₂ aerogel (ATiO₂) with higher specific surface area S_{BET} can compete with P25, a mix of anatase and rutile TiO₂. This confirms what we already observed in the case of water splitting and can thus be extended to CO₂ photoreduction.

The performance of co-doped ATiO₂, namely ATiO₂: Nb, N (0.59 ± 0.03 mmol_{MeOH}/g_{cat}/h) is much higher than that of ATiO₂ (0.03 ± 0.01 mmol_{MeOH}/g_{cat}/h). Doping with Nb and N improved MeOH production, probably due to the decrease of the bandgap resulting from changes in both the VB and CB energy levels in TiO₂.

The same level of performance can be reached with copper-loaded ATiO₂, Cu/ATiO₂ (0.66 ± 0.04 mmol_{MeOH}/g_{cat}/h). Here, the improvement may come from the ability of Cu_xO to improve the electron transfer efficiency during the reaction. Hence, we can conclude that both modifications have a similar impact on the performance even though their light absorption capacity is different. This also confirms that the mechanisms at work are much probably different.

Mixing both modifications has proven to be highly beneficial. Indeed, Cu/ATiO₂: Nb, N showed the best MeOH yield (1.69 ± 0.05 mmol_{MeOH}/g_{cat}/h), just before Cu/ATiO₂: N (1.51 ± 0.05 mmol_{MeOH}/g_{cat}/h) and Cu/ATiO₂: Nb (1.10 ± 0.04 mmol_{MeOH}/g_{cat}/h). Both N and Nb had a beneficial effect on the production of

Fig. 9. Recycled use of Cu/ATiO₂: Nb, N for MeOH production from CO₂ photoreduction.

MeOH, but relatively, Cu/ATiO₂: N is more effective.

Looking back to Fig. 7 A, Cu/ATiO₂: N absorbs more light than Cu/ATiO₂: Nb. Moreover, XPS results showed that it has a higher Cu⁺/Cu²⁺ ratio, similar to that of Cu/ATiO₂: Nb, N, which could also account for higher MeOH yields, due to the better ability of Cu⁺ to favor the CO₂ hydrogenation process [71]. The same statement can be made for Cu/ATiO₂: Nb, N.

By comparing the production of MeOH on Cu/ATiO₂: Nb, N at different intervals of times during the reaction (Fig. 8B), the MeOH production rate was found to be the highest during the first hour after turning the light on (6 mmol/g/h). Then it gradually decreased to stabilize or so after 1 h (0.6 mmol/g/h). This will help to understand the reaction mechanism of CO₂ photocatalytic reduction.

We were also interested in the “recyclability” or reuse possibility of our catalyst. Fig. 9 shows the MeOH yields of Cu/ATiO₂: Nb, N tested 6 h, five times in a row. During the first runs, the MeOH yields slightly decreased from ~1.7 mmol/g_{cat}/h to ~1.30 mmol/g_{cat}/h in the third run before more or less stabilizing.

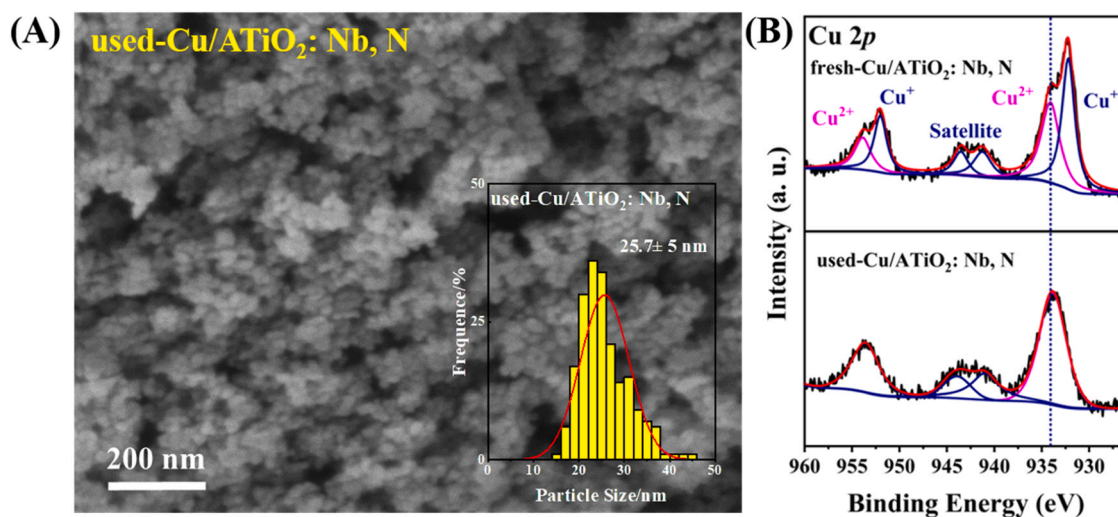

Fig. 10. (A) SEM image and Particle size distribution of used-Cu/ATiO₂: Nb, N and (B) Cu 2p XPS spectra of used-Cu/ATiO₂: Nb, N compare with fresh-Cu/ATiO₂: Nb, N.

Scheme 2. Proposed reaction mechanism over Cu/ATiO₂: Nb, N.

To investigate the possible reasons for the slight decrease observed, the used catalyst was analyzed.

Firstly, the SEM image (Fig. 10 A) shows that the used-Cu/ATiO₂: Nb, N did not agglomerate after testing, instead, it remained as uniform and dispersed small sizes (~26 nm). So the morphology of the aerogel support remained stable after the test, which may not be the reason for losing activity, and by the way, is good news for further long-term experiments.

Then the Cu 2p XPS spectrum of used-Cu/ATiO₂: Nb, N showed only Cu²⁺ species, whereas fresh-Cu/ATiO₂: Nb, N showed both Cu⁺ and Cu²⁺ species (Fig. 10B). This may partly explain the slight decrease in efficiency, caused by the conversion of Cu⁺ → Cu²⁺ on the catalyst surface during the reaction.

The mechanism of the photoreduction process is proposed, as shown in Scheme 2.

The photocatalytic process for converting CO₂ to methanol using Cu/ATiO₂: Nb, N involves a sequence of intricately linked steps, where both light absorption and charge separation are critical:

- **Light Absorption:** TiO₂ aerogel, when illuminated by the full-spectrum Xe lamp, absorbs photons across UV and visible wavelengths. This promotes electrons from the valence band to the conduction band, generating electron-hole pairs. The role of Nb and N doping here may extend beyond facilitating charge separation; it could also contribute to broadening the range of light absorption, particularly in the visible spectrum.
- **Oxidation of Water:** the process begins with the oxidation of water molecules or hydroxide ions on the TiO₂ surface, where the

Table 6

Methanol production reported in the literature.

Photocatalyst	Testing conditions	Methanol yield	Testing time	References
Cu _x O/ATiO ₂ : Nb, N	CO ₂ + Na ₂ CO ₃ solution room temperature	10.14 mmol/g _{cat} (1.69 mmol/g _{cat} /h)	6 h	this work
NH ₂ -MIL-125 (Ti)	CO ₂ + 0.2 M EDA room temperature	7 mmol/g _{cat} (1.75 mmol/g _{cat} /h)	4 h	[72]
2% Pd-Cu/TiO ₂	CO ₂ + H ₂ O 50 °C	0.56 mmol/g _{cat} (0.07 mmol/g _{cat} /h)	8 h	[73]
Cu (II) ZIF	CO ₂ + Na ₂ NO ₃ solution room temperature	1.71 mmol/g _{cat} (0.342 mmol/g _{cat} /h)	5 h	[74]

photogenerated holes in the valence band oxidize H₂O to O₂ and H⁺ ions (protons). This step is crucial as it supplies the protons necessary for the subsequent reduction of CO₂.

- **Role of Cu_xO Nanoparticles:** acting as cocatalysts, Cu_xO nanoparticles capture the separated electrons and facilitate their transfer to CO₂, enhancing the reduction process and the overall yield of methanol.
- **Reduction of CO₂:** the photogenerated electrons in the conduction band, now more efficiently separated, are transferred to the surface where they meet with CO₂ and the protons. It is the reaction between CO₂, protons, and electrons that leads to the formation of methanol.
- **Product Desorption:** the methanol product, once formed, desorbs from the aerogel surface, which is then collected from the reaction mixture.

Under dark conditions, as evidenced by our experiments listed in Table S3, no methanol production was detected, indicating that the reaction was light-driven. The high specific surface area of the TiO₂ aerogels contributes to the efficient adsorption of CO₂ and provides ample active sites for the reaction, while Nb and N doping, along with Cu_xO loading, collectively improve the TiO₂'s optical properties and charge carrier dynamics, crucial for the effective photoreduction of CO₂ to methanol.

Finally, we compared our work to reported ones in the literature and

realized in similar testing conditions, as far as the comparison is possible (See Table 6).

Our photocatalyst could reach the best performance ever published, in a longer period of time.

4. Conclusions

In conclusion, Cu_xO-loaded, Nb, and N co-doped TiO₂ aerogels (Cu/ATiO₂: Nb, N) were synthesized by the sol-gel method, supercritical CO₂ drying, and gas phase doping. ATiO₂ showed an anatase phase with particle size around 20–30 nm. Cu_xO was uniformly distributed on the TiO₂ surface with particle size < 2 nm. Nb and N doping enhanced the light absorption properties of TiO₂ and narrowed its bandgap. Loading with Cu_xO improved the electron transfer efficiency and the visible light absorption ability.

Applied for CO₂ photocatalytic reduction, Cu/ATiO₂: Nb, N has shown to have the best performance and the highest MeOH yield (1.69 ± 0.05 mmol/g_{cat}/h). This can be ascribed to several factors: i) improved optical properties after doping; ii) uniform distribution of Cu species in the surface and bulk of TiO₂; iii) high specific surface area and particle connectivity resulting from the peculiar aerogel morphology. These factors all contribute to enhancing the performance of TiO₂ for CO₂ reduction and MeOH production.

The finding that Cu/TiO₂ with Nb and N co-doping has the best performance in CO₂ reduction and the highest MeOH yield is very promising. This material could be a highly effective photocatalyst for the CO₂ reduction process. Further research and development on the aerogel morphology or N-doping will lead to the optimization of this material for such an application. The stability was revealed to be quite good but can however be improved, for example through stabilization of Cu⁺ on the catalyst surface.
